Quantum Circuits with Mixed States

Dorit Aharonov*   Alexei Kitaev†   Noam Nisan‡

Abstract

Current formal models for quantum computation deal only with unitary gates operating on "pure quantum states". In these models it is difficult or impossible to deal formally with several central issues: measurements in the middle of the computation; decoherence and noise, using probabilistic subroutines, and more. It turns out, that the restriction to unitary gates and pure states is unnecessary. In this paper we generalize the formal model of quantum circuits to a model in which the state can be a general quantum state, namely a mixed state, or a "density matrix", and the gates can be general quantum operations, not necessarily unitary. The new model is shown to be equivalent in computational power to the standard one, and the problems mentioned above essentially disappear.

The main result in this paper is a solution for the subroutine problem. The general function that a quantum circuit outputs is a probabilistic function. However, the question of using probabilistic functions as subroutines was not previously dealt with, the reason being that in the language of pure states, this simply can not be done. We define a natural notion of using general subroutines, and show that using general subroutines does not strengthen the model.

As an example of the advantages of analyzing quantum complexity using density matrices, we prove a simple lower bound on depth of circuits that compute probabilistic functions. Finally, we deal with the question of inaccurate quantum computation with mixed states. Using the so called "trace metric" on density matrices, we show how to keep track of errors in the new model.

1   Introduction

In the last few years theoretical computer scientists have started studying "quantum computation". The idea, which originates with Feynman [5], may be summarized as follows: the behavior of quantum physical systems seems to require exponential time to simulate on a (randomized) Turing machine. Hence, possibly, we could use physical computers built by relying on quantum physical laws to get an exponential speedup, for some computational problems, over normal (even randomized) Turing machines. If true, then this contradicts what may be called the modern Church-Turing thesis: "randomized Turing machines can simulate, with polynomial slowdown, any computation device".

Deutsch formalized Feynman's idea, and defined computational models of "quantum Turing machines" and "quantum circuits" [4]. These are extensions of the classical models of Turing machines and circuits, that take into account the laws of quantum physics. Deutsch's model, augmented with further work [3, 14], enabled a sequence of results [2, 13, 6] culminating with Shor's polynomial quantum algorithm for factoring integers [12]. However, it seems that Deutsch's model is incomplete in some key aspects which make working formally within it rather awkward. It seems that there is still a gap between the physical world and the formal definitions, which often leads computer scientists to bring physical phenomena into the model through the back door.

Let us recall the basic definitions used in current models for quantum computation: The device operates on n quantum-bits ("qubits"). Each one of the 2^n possible Boolean configurations $i \in \{0,1\}^n$ of these bits denotes a *basic state* $|i>$. The state of the computation at any point in time is a *superposition* of basic states $\sum_{i \in \{0,1\}^n} c_i |i>$, where the c_i's are complex numbers satisfying $\sum_i |c_i|^2 = 1$ (i.e. $\|c\| = \|c\|_2 = 1$). These superpositions are called *pure states*. Each computational operation is (1) *local:* i.e. involves only a constant number of qubits (2) *unitary:* i.e. maintains $\|c\| = 1$. At the end of the computation a *measurement* of one qubit is made, which returns a Boolean

value "true" with probability $\sum_{i,|i> \in M} |c_i|^2$, where M is a subspace of $\mathcal{C}^{(\{0,1\}^n)}$ specified by the measurement. The state changes (in a well defined way) according to the outcome of this measurement, and becomes a probability distribution over pure states.

Let us consider the model described above. During the computation, the operations must be unitary, and the state must be a pure state. But at the end of the computation, a non-unitary operation, a measurement, is applied, and the state becomes a probabilisty distribution over pure states, or what is called a mixed state. So we find out that in quantum physics operations might also be non-unitary, and states are not nesssecarily pure states. Restricting the model to unitary gates and pure states seems arbitrary. It is natural to ask: what is the most general model that captures quantum physics? In this paper we define a quantum circuit which is allowed to be in a general quantum states,i.e. a mixed state, and which is allowed to use any quantum operation as a gate, not necessarily unitary. Our first result is a simple corollary of known results in physics: [7]:

Theorem 1 *The model of quantum circuits with mixed states is polynomially equivalent in computational power to the standard unitary model.*

There are several key issues, which we find inconvenient, difficult, or impossible to deal with inside the standard, unitary model. In the non-unitary model of quantum circuits with mixed states, these problems essencialy disappear.

- **Measurements in the middle of computation:** it has been often remarked, and implicitly used (e.g. Shor's algorithm), that quantum computations may allow measurements in the middle of the computation. However, the state of the computation after a measurement is a mixed state, which is not allowed in the standard model. This problem no longer exists in our model.

- **Noise and Decoherence:** Noise and decoherence are key obstacles in implementing quantum computers devices. Recent results show that theoretically, fault tolerant computation exists[11, 1, 10, 9]. Still, in the task of realizing quantum computers, it is likely that more theoretical work will be needed in this direction. A key problem in this interface between quantum physics and quantum computation models is the fact that quantum noise, and in particular, decoherence, are non-unitary operations that cause a pure state to become a mixed state. Incorporating quantum

noise, which was impossible in the standard unitary model, is naturally done in our model.

The main technical result of this paper is a soulution of one more problem in the unitary model, namely the **subroutine problem**. A cornerstone of computer science is the notion of using subroutines (or oracles, or reductions): once we are able to perform an operation A within our model, we should be able to use A as a "black box" in further computations. The general and natural function that a quantum computer outputs is a *probabilistic function:* for an input X, the output is distributed according to a distribution, D_X, which depends on the input. When using such a probabilistic function as a subroutine, the state is affected in a non-unitary manner. Therefore, using subroutines in their full generality was never defined in the unitary model. This is an incompleteness of the current model, because computatble functions can not be used as "black boxes".

The special case of using deterministic subroutines was defined in[2], and it was shown that using determinstic subroutines does not strengthen the model. As to probabilistic subroutines, these were implicitly used in quantum algorithms,(e.g. Shor's algorithm,) but always on a classical input, for this case can be easily understood. A conceptual difficulty lies in the combination of applying *probabilistic* subroutines to quantum *superpositions*. It is not clear what the natural definition should be. Here, we are able to give a natural definition which generalises both the case of deterministic subroutines on superpositions, and the case of probabilistic subroutines on classical inputs. We prove that using general subroutines does not strengthen the model. Let us define FQP to be the set of probabilistic fuctions computed by uniform quantum circuits with polynomial size and depth. Our main result is:

Theorem 2 $FQP^{FQP} = FQP.$

We hope that this new tool will be useful in quantum algorithms.

As to the formalism, it turns out that the description of the state of the circuit by a probability distribution over pure states is not unique. Physicists use an alternative unique description, namely density matrices, which provides many conceptual and practical advantages. In this paper, we give all definitions and proofs using the density matrix picture. As an example of the benefits of dealing with quantum complexity questions with density matrices, we provide a simple lower bound on the depth of a circuit which computes probabilistic functions. The same lower bound seems difficult to prove when using the standard language of pure states.

A crucial point in a computation model is understanding how inaccuracies in the basic computational elements affect the correctness of the computed function. In order to keep track of the error in the function computed by a circuit in a mixed state, one needs appropriate metrics on probabilistic functions, density matrices and gates. For probabilistic functions, we use a natural metric,relying on total variation distances.As a metric on density matrices, we propose to use the *trace metric*, induced by the *trace norm*: $\|H\| = \sum_i |\lambda_i|$, where λ_i are the eigenvalues of H. We show that it is an appropriate metric since it quantifies the *measurable distance between two quantum states*. We also define a metric on quantum gates which has very nice properties. An *error* in a function, a gate, or a density matrix will be the distance (in the corresponding metrics) from the correct function, gate, or density matrix, respectively. Using the above metrics, we establish the following fact:

Theorem 3 *Let Q be a quantum circuit which uses L probabilistic subroutines and gates, each with at most ϵ error. The function that Q computes has at most $O(L\epsilon)$ error.*

Organization of Paper In section 2 we provide the physical background, in a mathematical language. In section 3 we define our model. Section 4 provides the basic theorems regarding the model, and includes an example of complexity bound using density matrices. Section 5 discusses the metrics and errors.

2 Some Useful Physics Background

The model of Quantum computers is based on the rules of quantum mechanics. A good reference for basic rules is [8].

Pure states: A quantum physical system in a *pure state* is described by a unit vector in a Hilbert space, i.e a vector space with an inner product. In the *Dirac* notation a pure state is denoted by $|\alpha\rangle$. The physical system which corresponds to a quantum circuit consists of n quantum two-state particles, and the Hilbert space of such a system is $\mathcal{H}_2^n = \mathcal{C}^{\{0,1\}^n}$ i.e. a 2^n dimensional complex vector space. $\mathcal{H}_2^n$ is viewed as a tensor product of n Hilbert spaces of one two-state particle: $\mathcal{H}_2^n = \mathcal{H}_2 \otimes \mathcal{H}_2 \otimes \ldots \otimes \mathcal{H}_2$. The k'th copy of $\mathcal{H}_2$ will be referred to as the k'th **qubit**. We choose a special basis for $\mathcal{H}_2^n$, which is called the computational basis. It consists of the 2^n orthogonal states: $|i\rangle, 0 \le i < 2^n$, where i is in binary representation. $|i\rangle$ can be seen as a tensor product of states in $\mathcal{H}_2$: $|i\rangle = |i_1\rangle|i_2\rangle\ldots|i_n\rangle = |i_1 i_2..i_n\rangle$, where each i_j gets 0 or 1. Such a state, $|i\rangle$, corresponds to the j'th particle being in the state $|i_j\rangle$. A

pure state $|\alpha\rangle \in \mathcal{H}_2^n$ is generally a *superposition* of the basis states: $|\alpha\rangle = \sum_{i=1}^{2^n} c_i |i\rangle$, with $\sum_{i=1}^{2^n} |c_i|^2 = 1$. A vector in $\mathcal{H}_2^n$, $v_\alpha = (c_1, c_2, ..., c_{2^n})$, written in the computational basis representation, with $\sum_{i=1}^{2^n} |c_i|^2 = 1$, corresponds to the pure state: $|\alpha\rangle = \sum_{i=1}^{2^n} c_i |i\rangle$. $v_\alpha^\dagger$, the transposed-complex conjugate of v_α, is denoted $\langle\alpha|$. The inner product between $|\alpha\rangle$ and $|\beta\rangle$ is denoted $\langle\alpha|\beta\rangle = (v_\alpha^\dagger, v_\beta)$. The matrix $v_\alpha^\dagger v_\beta$ is denoted as $|\alpha\rangle\langle\beta|$.

Mixed state: In general, a quantum system is not in a pure state. This may be attributed to the fact that we have only partial knowledge about the system, or that the system is not isolated from the rest of the universe, so it does not have a well defined pure state. We say that the system is in a *mixed state*, and assign with the system a probability distribution, or *mixture* of pure states, denoted by $\{\alpha\} = \{p_k, |\alpha_k\rangle\}$. This means that the system is with probability p_k in the pure state $|\alpha_k\rangle$. This description is not unique, as different mixtures might represent the same physical system. As an alternative description, physicists use the notion of **density matrices**, which is an equivalent description but has many advantages. A density matrix ρ on $\mathcal{H}_2^n$ is an hermitian (i.e. $\rho = \rho^\dagger$) semi positive definite matrix of dimension $2^n \otimes 2^n$ with trace $\text{Tr}(\rho) = 1$. A pure state $|\alpha\rangle = \sum_i c_i |i\rangle$ is represented by the density matrix: $\rho_{|\alpha\rangle} = |\alpha\rangle\langle\alpha|$, i.e. $\rho_{|\alpha\rangle}(i,j) = c_i c_j^*$. (By definition, $\rho(i,j) = \langle i|\rho|j\rangle$). A mixture $\{\alpha\} = \{p_l, |\alpha_l\rangle\}$, is associated with the density matrix $\rho_{\{\alpha\}} = \sum_l p_l |\alpha_l\rangle\langle\alpha_l|$. This association is not one-to-one, but it is onto the density matrices, because any density matrix describes the mixture of it's eigenvectors, with the probabilities being the corresponding eigenvalues. Note that diagonal density matrices correspond to probability distributions over classical states. Density matrices are linear operators on their Hilbert spaces. The following notations will be used: if $\mathcal{N}$ is a finite-dimensional Hilbert space then $L(\mathcal{N})$ is the set of all linear operators on $\mathcal{N}$. Also, $L(\mathcal{N}, \mathcal{M})$ stands for the set of linear operators $\mathcal{N} \to \mathcal{M}$.

A density matrix of n qubits can be reduced to a subset, A, of $m < n$ qubits. We say that the rest of the system, represented by the Hilbert space $\mathcal{F} = \mathcal{C}^{2^{n-m}}$, is *traced out*, and denote the new matrix by $\rho|_A = \text{Tr}_\mathcal{F} \rho$. It is defined as follows: $\rho|_A(i,j) = \sum_{k=1}^{2^{n-m}} \rho(ik, jk)$. Actually, the partial trace $\text{Tr}_\mathcal{F} : L(\mathcal{N} \otimes \mathcal{F}) \to L(\mathcal{N})$ is defined for any pair of finite-dimensional Hilbert spaces $\mathcal{N}$ and $\mathcal{F}$. In words, it means averaging over $\mathcal{F}$. Any quantum operation which does not operate on $\mathcal{F}$ commutes with this tracing out.

Operations on quantum states Transformations

of density matrices are linear operators on operators (sometimes called *superoperators*). Any physically allowed superoperator $T : L(\mathcal{N}) \to L(\mathcal{M})$ sends density matrices to density matrices. This is equivalent to say that T is positive and trace-preserving. (A superoperator is called *positive* if it sends positive semidefinite Hermitian matrices to positive semi-definite Hermitian matrices). However, this is not enough for a superoperator to be physically allowed. The positivity must remain if we extend the spaces $\mathcal{N}$ and $\mathcal{M}$ by adding more qubits. That is, the superoperator $T \otimes I_{\mathcal{F}}$ must be positive, where $I_{\mathcal{F}}$ is the identity superoperator on an arbitrary finite-dimensional Hilbert space $\mathcal{F}$. Such T is called a *completely positive map*. Hence physically allowed quantum operations are linear trace preserving completely positive maps. Clearly, linear operations on mixed states preserve the probabilistic interpretation of the mixture, because $T \circ \rho = T \circ (\sum_l p_l |\alpha_l\rangle\langle\alpha_l|) = \sum_l p_l T \circ (|\alpha_l\rangle\langle\alpha_l|)$.

One example for a superoperator is the partial trace map which we defined before, $\mathrm{Tr}_{\mathcal{F}} : L(\mathcal{N} \otimes \mathcal{F}) \to L(\mathcal{N})$. Another very important example is a *unitary embedding* $V : \mathcal{N} \to \mathcal{M}$. This defines the superoperator $T : \rho \mapsto V\rho V^\dagger$. A unitary embedding naturally appears when we add a blank qubit to the system, $V_0 : |\xi\rangle \mapsto |\xi\rangle \otimes |0\rangle : C^{2^n} \to C^{2^{n+1}}$. It turns out that any physically allowed superoperator is a combination of these two.

The following lemma provides the link between superoperators and standard unitary operations. It turns out that any superoperator from n to m qubits is equivalent to the operation of a unitary matrix on $2n + m$ qubits.

lemma 1 *(modification of Choi (1970),Hellwig and Kraus(1975), and Schumacher (1996)[7]): The following conditions are equivalent:*

1. *A superoperator $T : L(\mathcal{N}) \to L(\mathcal{M})$ is trace-preserving and completely positive.*

2. *There is a Hilbert space $\mathcal{F}$ with $\dim(\mathcal{F}) \leq \dim(\mathcal{N})\dim(\mathcal{M})$, and a unitary embedding $V : \mathcal{N} \to \mathcal{N} \otimes \mathcal{F}$ such that $T\rho = \mathrm{Tr}_{\mathcal{F}}(V\rho V^\dagger) \; \forall \rho \in L(\mathcal{N})$.*

A superoperator corresponding to a unitary transformation on a space $\mathcal{N}$, $|\alpha \rangle \mapsto U|\alpha \rangle$, sends a quantum state $\rho = |\alpha\rangle\langle\alpha|$ to the state $U\rho U^\dagger$. Such a superoperator is denoted by $U \cdot U^\dagger$. This is one important of a physically realizable superoperator, and corresponds to the standard unitary operations.

Superoperators can be extended to operate on larger spaces by taking tensor product with the identity operator: $T : L(\mathcal{N}) \to L(\mathcal{M})$ will be extended to

$T \otimes I : L(\mathcal{N} \otimes \mathcal{R}) \to L(\mathcal{M} \otimes \mathcal{R})$. Usually, we will be interested in those superoperators that are extensions of superoperators on spaces with small dimensionality. This will correspond to local gates later on.

In order to describe the operation of superoperators on density matrices $\in L(\mathcal{N})$ is suffices, from linearity, to specify what happens to a basis which spans the density matrices: $\{|i\rangle\langle j|\}_{i,j}$ where $|i\rangle$, $\langle j|$ run over all basis vectors of $\mathcal{N}$. (Any density matrix can be written as $\rho = \sum_{i,j} \rho_{i,j}|i\rangle\langle j|$.) For example the unitary operation $|i\rangle \longmapsto |v_i\rangle$ corresponds to the superoperator specified by $|i\rangle\langle j| \longmapsto |v_i\rangle\langle v_j|$. If U is extended to $\in L(\mathcal{N} \otimes \mathcal{M})$ $|i, k\rangle\langle j, l| = |i\rangle\langle j| \otimes |k\rangle\langle l| \longmapsto (|v_i\rangle\langle v_j|) \otimes (|k\rangle, \langle l|)$.

Measurements A quantum system can be measured, or observed. Let us consider a set of positive semi-definite Hermitian operators $\{P_m\}$, such that $\sum_m P_m = I$. The measurement is a process which yields a probabilistic classical output. For a given density matrix ρ, the output is m with probability $\mathrm{Pr}(m) = \mathrm{Tr}(P_m\rho)$.

We will use only *projection* measurements. Namely, we assume that P_m are orthogonal projections onto mutually orthogonal subspaces S_m which span the whole space $\mathcal{N} = C^{2^n}$, i.e. $\mathcal{N} = \bigoplus_m S_m$. A more particular type of measurement which we will be using a lot is a basic measurement of r qubits. In this case, P_m (with $1 \leq i \leq 2^r$) are the projection on the subspace S_m, which is the subspace spanned by basic vectors on which the measured qubits have the values corresponding to the string m: $S_m = \mathrm{span}\{|m, j\rangle, \; j = 1, \ldots, 2^{n-r}\}$. This process corresponds to measuring the value of r qubits, in the basic basis, where here, for simplicity, we considered measuring the first r qubits.

The classical result of a measurement, m, can be represented by the density matrix $|m\rangle\langle m|$ in an appropriate Hilbert space $\mathcal{M}$. The state of the quantum system after a projection measurement is also defined; it is equal to $\mathrm{Pr}(m)^{-1}P_m\rho P_m$. (It has the same meaning as a conditional probability distribution). Thus, the projection measurement can be described by a superoperator T which maps quantum states on the space $\mathcal{N}$ to quantum states on the space $\mathcal{N} \otimes \mathcal{M}$, the result being diagonal with respect to the second variable:

$$T\rho = \sum_m (P_m\rho P_m) \otimes \Big(|m\rangle\langle m|\Big)$$

3 Quantum Circuits with Mixed States

We define here a model of quantum circuits, using density matrices. This enables us to apply general non-unitary gates. The circuit is defined to compute probabilistic functions, which are a generalization of Boolean

functions computed by a standard quantum circuit. A quantum gate is defined to be the most general quantum operation:

definition 1 *A quantum gate, g, of order (k, l) is a trace preserving, completely positive, linear map from density matrices on k qubits to density matrices on l qubits. Its action on the density matrices is denoted as follows: $\rho \longmapsto g \circ \rho$. (The "$\circ$" sign is used for clarity and could be omitted).*

The unitary gate, U, of the standard model is a special case of a quantum gate. The corresponding superoperator is $U \cdot U^\dagger$. Using our "$\circ$" notation, we can denote it simply by U with no danger of confusion. Thus, $U \circ \rho = U \rho U^\dagger$.

A measurement is also a special case of a quantum gate — the probabilistic projection onto a set of mutually orthogonal subspaces. Besides changing the state of the qubits, it produces a classical probabilistic result. (As shown above, both results can be described by a joint density matrix, but it is better to take the advantage of the second result being classical).

We now define a quantum circuit:

definition 2 *Let $\mathcal{G}$ be a family of quantum gates. A Quantum circuit that uses gates from $\mathcal{G}$ is a directed acyclic graph. Each node v in the graph is labeled by a gate $g_v \in \mathcal{G}$ of order (k_v, l_v). The in-degree and out-degree of v are equal k_v and l_v, respectively. An arbitrary subset of the inputs are labeled "blank". An arbitrary subset of the outputs are labeled "result".*

Here is a schematic example of such a circuit. We use "b", "r" for "blank", "result".
The circuit operates on a density matrix as follows:

definition 3 final density matrix: *Let Q be a quantum circuit. Choose a topological sort for Q: $g_t...g_1$. Where g_j are the gates used in the circuit. The final density matrix for an initial density matrix ρ is $Q \circ \rho = g_t \circ ... \circ g_2 \circ g_1 \circ \rho$.*

Usually there exists more than one topological sort for a given circuit Q. Yet $Q \circ \rho$ is well defined and operations of the gates in a quantum circuit determined by two different topological sorts are equivalent:

lemma 2 $g_t \circ ... \circ g_2 \circ g_1 \circ \rho = g_{\sigma(t)} \circ ... \circ g_{\sigma(2)} \circ g_{\sigma(1)} \circ \rho$, *where σ is a permutation, If the two orderings are two topological sorts of the same quantum circuit.*

The reason for this is that two gates that operate on different qubits commute. The proof of lemma 2 easily follows from:

lemma 3 *Let g_1, g_2 be two quantum gates operating on different qubits. Then $\forall \rho$, $g_1 \circ g_2 \circ \rho = g_2 \circ g_1 \circ \rho$.*

Proof: To extend the gates to operate on the whole set of n qubits, we tensor with the identity. For simplicity, let us assume that g_1 operates on the first k_1 qubits (the Hilbert space $\mathcal{N}$), and g_2 operates on some of the rest of the qubits (the Hilbert space $\mathcal{M}$). We only need to show that $(g_1 \otimes I_\mathcal{M}) \circ (I_\mathcal{N} \otimes g_2) = g_1 \odot g_2$ and $(I_\mathcal{N} \otimes g_2) \circ (g_1 \otimes I_\mathcal{M}) = g_1 \odot g_2$. These are simply particular cases of the identity

$$(X_1 \otimes X_2)(Y_1 \otimes Y_2) = (X_1 Y_1) \odot (X_2 Y_2)$$

where X_1, Y_1 and X_2, Y_2 act on arbitrary linear two spaces. (The "$\circ$" signs are omitted here). ∎

Now we are ready to define the function that the circuit computes. The circuit produces a probability distribution over strings of r bits, which depends on it's input string. The probability distribution is computed out of the final density matrix, and is the same probability distribution as one would get over the strings of outcomes, if at the end of the computation we apply a basic measurement of all the "result" qubits.

definition 4 Computed function: *Let Q be a quantum circuit, with n inputs and r "result" outputs. The probabilistic function that Q computes, $f_Q = f$: $\{0,1\}^n \longmapsto [0,1]^{\{0,1\}^r}$, is defined as follows: For input i, the probability for output j is $f_{i,j} = \langle j | \left(Q \circ |i\rangle\langle i| \right)\big|_A |j\rangle$, where A is the set of the "result" outputs.*

4 Results

In this section we provide the theorems which prove that the model is equivalent to the standard model and that it allows using probabilistic subroutines. We also provide a simple lower bound on the depth of circuits computing probabilistic functions.

4.1 Substituting General Gates by Unitary Gates

General non-unitary gates can be replaced by unitary gates, as is shown by the following lemma:

lemma 4 *Let g be a quantum gate of order (n, m). There exists a unitary quantum gate U_g on $2n + m$ qubits which satisfies: For any ρ, $g \circ \rho = \left(U_g \circ \left(\rho \otimes |0^{n+m}\rangle\langle 0^{n+m}| \right) \right)\Big|_A$, where A is the set of the first m qubits.*

Proof: This lemma follows from lemma 1. By definition 1, the gate g is a trace-preserving completely positive superoperator $L(\mathcal{N}) \to L(\mathcal{M})$, where $\mathcal{N} = \mathcal{C}^{2^n}$ and $\mathcal{M} = \mathcal{C}^{2^m}$. By lemma 1, it has a representation of the form $g = \text{Tr}_{\mathcal{F}}(V \cdot V^\dagger)$, where $\mathcal{F} = \mathcal{C}^{2^{n+m}}$, and $V : \mathcal{N} \to \mathcal{M} \otimes \mathcal{F}$ is a unitary embedding. Let us choose an orthonormal basis $\{|\eta_{i,j}\rangle,\ 1 \le i \le 2^n,\ 1 \le j \le 2^{n+m}\}$ in $\mathcal{M} \otimes \mathcal{F}$, such that $|\eta_{i,0^{n+m}}\rangle = V|i\rangle$ for any i (the other basis vectors are arbitrary). There is a unique unitary operator U which sends each vector $|i, j\rangle$ of the basic basis to the vector $|\eta_{i,j}\rangle$ of the new basis. It is obvious that $V = UV_0$, where $V_0 : |\xi\rangle \mapsto |\xi\rangle \otimes |0^{n+m}\rangle$. Hence $g = \text{Tr}_{\mathcal{F}}(UV_0 \cdot V_0^\dagger U^\dagger)$. This is what we need. ∎

It follows that a circuit with general gates can be simulated by a circuit with unitary gates efficiently:

Theorem 1: *The model of quantum circuits with mixed states is polynomially equivalent in computational power to the standard model.*

4.2 Using General Subroutines

A (probabilistic) subroutine is a function, $f : \{0, 1\}^m \mapsto R^{\{0,1\}^p}$, which outputs j with distribution which depends on the input i. A quantum circuit that uses subroutines is a circuit in which a node of fan-in=fan-out=$m + p$ may be associated instead of a quantum gate, a probabilistic function $f : \{0, 1\}^m \mapsto R^{\{0,1\}^p}$. Our definition of the way this "subroutine gate", denoted by g_f, effects the density matrix is by operating all possible deterministic functions, in the standard way, where each deterministic function is applied with the induced probability from the probabilistic function:

definition 5 operation of a subroutine gate:

$$g_f \circ \rho = \sum_d \Pr(d) U_d \rho U_d^\dagger$$

Where the sum is over all deterministic functions $d : \{0, 1\}^m \mapsto \{0, 1\}^p$, U_d is defined by $U_d|i, 0\rangle = |i, d(i)\rangle$ and the induced probability for d is:

$$\Pr(d) = \prod_i \text{Prob}(i \mapsto d(i)) = \prod_i f_{i,d(i)}.$$

Note that as discussed in the introduction, this definition generalizes both the case of deterministic subroutines on superpositions, and the case of probabilistic subroutines on classical inputs. The sum contains 2^{p2^m} summands. It turns out that the same operation on density matrices can be written in a much more compact form.

lemma 5

$$g_f \circ (|i_1, 0\rangle\langle i_2, 0|) = \qquad (1)$$
$$\begin{cases} \sum_j f_{ij} |i, j\rangle\langle i, j| & \text{if } i_1 = i_2 = i \\ \sum_{j_1, j_2} f_{i_1 j_1} f_{i_2 j_2} |i_1, j_1\rangle\langle i_2, j_2| & \text{if } i_1 \ne i_2 \end{cases}$$

Proof:

$$\sum_d \Pr(d) U_d |i_1, 0\rangle\langle i_2, 0| U_d^\dagger =$$

$$\sum_d \Pr(d) |i_1, d(i_1)\rangle\langle i_2, d(i_2)| =$$

$$\sum_{j_1, j_2} \Big(\sum_{d, d(i_1)=j_1, d(i_2)=j_2} \Pr(d) \Big) |i_1, d(i_1)\rangle\langle i_2, d(i_2)|.$$

We now compute the term in the brackets. If $i_1 = i_2$, it becomes:

$$\delta(j_1, j_2) \sum_{d, d(i_1)=j_1} \prod_i \text{Prob}(i \mapsto d(i)) =$$
$$\delta(j_1, j_2) f_{i_1, j_1} \sum_{j_i, i \ne i_1} \prod_i f_{i, j_i} = \delta(j_1, j_2) f_{i_1, j_1}.$$

If $i_1 \ne i_2$, then the same computation yields

$$\sum_{d, d(i_1)=j_1, d(i_2)=j_2} \prod_i \text{Prob}(i \mapsto d(i)) =$$
$$f_{i_1, j_1} f_{i_2, j_2} \sum_{j_i, i \ne i_1, i \ne i_2} \prod_i f_{i, j_i} = f_{i_1, j_1} f_{i_2, j_2}. \ ∎$$

Before we state our main theorem, here are some notations: For a family of gates $\mathcal{G}$ we denote by $\mathcal{U}_{\mathcal{G}}$ the set of unitary gates corresponding to gates from $\mathcal{G}$, according to lemma 4. We denote by $\mathcal{U}_{\mathcal{G}}^\dagger$ the set of daggered unitary gates corresponding to gates from $\mathcal{G}$. C is a special unitary gate on two qubits, the *controlled not gate*. It satisfies $C|00\rangle = |00\rangle, C|10\rangle = |11\rangle$, and thus serves as a copying gate.

Theorem 2: $FQP^{FQP} = FQP$: *Let $\mathcal{G}$ be a set of gates, $\mathcal{S}$ a set of probabilistic functions from m to r bits, computable by quantum circuits using no more than k gates from $\mathcal{G}$. Let Q be a quantum circuit, which*

uses n gates from $\mathcal{G}$, and l subroutines from $\mathcal{S}$, there exists a quantum circuit $\tilde{Q}$ which uses no more then $n + l(O(k) + O(r) + O(m))$ gates from $\mathcal{U_G} \cup \mathcal{U_G^{\dagger}} \cup \mathcal{C}$ and computes f_Q.

Proof: We now show that a subroutine $s \in S$, for $s : \{0,1\}^m \longmapsto R^{\{0,1\}^r}$, can be replaced by $O(k) + O(r) + O(m)$ gates from $\mathcal{U_G} \cup \mathcal{U_G^{\dagger}} \cup \mathcal{C}$. The idea is to apply Q_s, read the result by copying it to extra r qubits, and undo the subroutine. Up till now, this is just following the line of the proof for deterministic subroutines[2]. However, this is not enough when dealing with probabilistic functions. The reason, intuitively, is that in probabilistic subroutines there is more than one possible output for one input, so the state of the bits that are used to copy the output, is not in tensor product with that of the input and output bits, even if the input was classical. Hence, undoing the subroutine does not take the input bits back to their original input state. The reader is urged to try and see for herself why more effort is needed. We proceed by the following operations: We add $m + 1$ blank qubits to the circuit. The last bit will be a *garbage controll* bit. First, we check if there is garbage left, i.e. if the string written on the qubits other than the main qubits is different from zero, and if so, we change the *garbage control* bit to $|1\rangle$. Then, conditioned that the garbage control bit is one, we copy the *input* m bit string of the subroutine to m ancilla bits. If there is no garbage, we leave the ancilla bits to be blank. Then we trace out, or discard, the garbage and the $m+1$ ancilla bits. This procedure results with the same operation as the subroutine gate, g_s, and we have used $O(k) + O(r) + O(m)$ gates.

Let us agree on some notation before continuing: Let the subroutine s be computed by the circuit Q_s, which uses only unitary gates from $\mathcal{U_G}$, using theorem 4. Thus the operation of Q_s is unitary, and is described by the unitary matrix $U_s = U$. So the final density matrix of Q_s is a density matrix of a pure state, which can be written as $U|i,0\rangle$ for an input i, and r blank qubits. We can write:

$$U|i,x\rangle = |i\rangle \otimes U_i|x\rangle$$

$$U_i|0\rangle = \sum_j |j\rangle \otimes |\psi_{ij}\rangle \qquad \text{where} \quad \langle\psi_{ij}|\psi_{ij}\rangle = f_{ij}$$

Let us track the procedure step by step. We will do that by seeing what happens to a matrix of the form $|i_1\rangle\langle i_2|$. From linearity, this will be enough.

$$U|i,0\rangle = \sum_j |i\rangle \otimes |j,\psi_{ij}\rangle$$

When j is copied, the above expression becomes

$$\sum_j |i,j\rangle \otimes |j,\psi_{ij}\rangle$$

The first two registers will be referred to as the *qubits*, and the last two registers will be discarded later. Then $U^{-1} = U^{\dagger}$ is applied which yields

$$|\xi_i\rangle = \sum_j |i,j\rangle \otimes U_i^{\dagger}|j,\psi_{ij}\rangle$$

Let us represent $|\xi_i\rangle$ as $|\eta_i\rangle + |\nu_i\rangle$, where

$$|\eta_i\rangle = \sum_j \langle 0|U_i^{\dagger}|j,\psi_{ij}\rangle |i,j\rangle \otimes |0\rangle$$

corresponds to the possibility of having no garbage, and $|\nu_i\rangle = |\xi_i\rangle - |\eta_i\rangle$ is orthogonal to $|\eta_i\rangle$). Note that $\langle 0|U_i^{\dagger}|j,\psi_{ij}\rangle = \langle\psi_{ij}|\psi_{ij}\rangle = f_{ij}$, so

$$|\eta_i\rangle = f_{ij}|i,j\rangle \otimes |0\rangle$$

We now add the step of computing the state of the control garbage qubit, and conditioned on that coping the input. The overall procedure can be represented as follows

$$|i\rangle \mapsto |\eta_i, no, 0\rangle + |\nu_i, yes, i\rangle$$

where *no* and *yes* are states of the controlled garbage bit. As long as the garbage and the ancilla bits are discarded, i.e. the reduced density matrix on the original set of qubits (denote it by Q) is taken, we have:

$$|i_1\rangle\langle i_2| \mapsto$$

$$(|\eta_{i_1}, no, 0\rangle + |\nu_{i_1}, yes, i\rangle)((\langle\eta_{i_2}, no, 0| + \langle\nu_{i_2}, yes, i|)|_Q =$$

$$= (|\eta_{i_1}\rangle\langle\eta_{i_2}|)|_Q + (|\nu_{i_1}\rangle\langle\nu_{i_2}|)|_Q \delta_{i,j}$$

For $i_1 \neq i_2$, we have:

$$= \sum_{j_1,j_2} f_{i_1 j_1} f_{i_2 j_2} |i_1, j_1\rangle\langle i_2, j_2|$$

For $i_1 = i_2$, we have to go few steps back in our calculations. Recall that the vectors $|\eta_i\rangle$ and $|\nu_i\rangle$ were defined in such a way that $(|\eta_i\rangle\langle\nu_i|)|_Q = 0$ (because $|\eta_i\rangle$ corresponds to no garbage whereas $|\nu_i\rangle$ corresponds to non-null garbage). Hence

$$(|\eta_i\rangle\langle\eta_i| + |\nu_i\rangle\langle\nu_i|)|_Q = (|\xi_i\rangle\langle\xi_i|)|_Q$$

$$= \sum_{j,j'} \langle j', \psi_{ij'}|U_i U_i^{\dagger}|j, \psi_{ij}\rangle |i,j\rangle\langle i, j'| =$$

$$= \sum_j f_{ij}|i,j\rangle\langle i,j|.$$

Thus we have the desired transformation. ∎

4.3 Simple Lower Bounds on Probabilistic Functions

We prove a lower bound on probabilistic functions. The proof relies on *causality*, which can be stated as follows. Consider a quantum circuit Q, and two qubits a and b. The two bits are correlated only if there is a gate from which there is a path to them both. This will imply a lower bound on probabilistic functions where one qubit is correlated to many others.

lemma 6 Causality lemma: *Let Q be a quantum circuit, with gates $g_t, ...g_1$. Let ρ be a density matrix of a basic state. If $Q \circ \rho|_{a,b}$ is not a tensor product, there exist i such that there are two (directed) paths in the circuit: $g_i \longmapsto a_f$ and $g_i \longmapsto b_f$.*

Proof: Let us assume that there is no i such that there are two (directed) paths in the circuit: $g_i \longmapsto a_f$ and $g_i \longmapsto b_f$. Let us now find a topological sort of all gates from which there is a directed path to a_f (and therefore not to b_f), and let us call this set of gates G_a. Let us sort the set G_b similarly, and the rest of the gates G_c also. We claim that the sort $G_c G_b G_a$ is a topological sort of the circuit. To show this, we need only show that if there is a path from g_i to g_j in the circuit, then g_j appears to the left of g_i. The only thing we have to check is that there is no path from gate g_c in G_c to any gate in G_a (G_b). But if there was such a path, then g_c would have belonged to G_a (G_b). Now, $(G_c \circ G_b \circ G_a \circ \rho)|_{a,b} = (G_b \circ G_a \circ \rho)|_{a,b}$ due to the following lemma:

lemma 7 *Let g be a gate operating on qubits not in the set B. $\rho|_B = (g \circ \rho)|_B$.*

proof: Let B be described by first indices, and g operates on the space described by second indices.

$$\rho = \sum_{i,k,j,l} \rho_{ik,jl}|i,k\rangle\langle j,l|, \quad \rho|_B = \sum_{i,j}(\sum_k \rho(ik,jk))|i\rangle\langle j|$$

To apply the gate g, we use the equivalent unitary gate U_g according to lemma 4.

$$g \circ \rho = \sum_{i,k,j,l} \rho_{ik,jl}|i\rangle\langle j| \otimes U_g|k\rangle\langle l|U_g^\dagger =$$

$$\sum_{i,j,k,l,k',l'} \rho_{ik,jl}|i\rangle\langle j| \otimes |k'\rangle\langle k'|U_g|k\rangle\langle l|U_g^\dagger|l'\rangle\langle l'|.$$

Computing the reduced density matrix we get:

$$g \circ \rho|_B = \sum_{i,j}|i\rangle\langle j|(\sum_{k,l,k'} \rho_{ik,jl}\langle k'|U_g|k\rangle\langle l|U_g^\dagger|k'\rangle,)$$

but $\sum_{k'}\langle k'|U_g|k\rangle\langle l|U_g^\dagger|k'\rangle = \langle l|U_g U_g^\dagger|k\rangle = \delta_{k,l}$.∎

The set of qubits A, B which G_a and G_b operate upon are disjoint, according to our assumption. Let A', B', be sets of qubits such that their union is all the qubits, and $A' \supseteq A$, $B' \supseteq B$. We can write:

$$(G_b \circ G_a \circ \rho)|_{a,b} = (G_b \circ G_a \circ (\rho|_{A'} \otimes \rho|_{B'}))|_{a,b} =$$

$$(G_a \circ \rho|_{A'}) \otimes (G_b \circ \rho|_{B'})|_{a,b} = (G_a \circ \rho|_{A'})|_a \otimes (G_b \circ \rho|_{B'})|_b.$$

Which shows that the final reduced density matrix is a tensor product. ∎

Let us define the correlation graph for a state:

definition 6 Correlation graph: *Given a state ρ of n qubits, we define the correlation graph $G_\rho(V, E)$ of the state as follows. The set of nodes V will consist of n nodes, corresponding to the n qubits. An edge $(a, b) \in E$ iff the reduced density matrix $\rho|_{a,b}$ is not a tensor product.*

We now claim that the depth of the circuit with final density matrix ρ is larger than the logarithm of the maximal degree in the correlation graph G_ρ.

lemma 8 *Let Q be a quantum circuit, with all gates of fan-in $\leq k$. Let the maximal degree of the correlation graph of $Q \circ |i\rangle$ be c, for some input i. Then the depth of Q satisfies $D(Q) \geq \frac{1}{2}log_k(c)$.*

Proof: By causality, if there is an edge in the correlation graph between qubits a, b then in the circuit there is a node g_i such that there are two (directed) paths in the circuit: $g_i \longmapsto a_f$ and $g_i \longmapsto b_f$. For a circuit of depth D, and a given qubit a, the maximal number of qubits which are connected to a in such a way are k^{2D}. So $c \leq k^{2D}$, and hence $D(Q) \geq \frac{1}{2}log_k(c)$.∎

The correlation graph can be defined for probabilistic functions as well. If the output is probabilistic string of r bits, it will be a graph of r nodes. Edges will connect pairwise correlated bits.

lemma 9 Correlation bound: *Let Q be a quantum circuit computing f, a probabilistic function. Let c be the maximal degree of the correlation graph of f. Then $D(Q) \geq log_k(c)$.*

As a trivial example, consider the probabilistic function that outputs (for any input) with probability $\frac{1}{2}$ the string 0^r and with probability $\frac{1}{2}$ the string 1^r. The lemma shows that a circuit that computes this function must be of depth larger than $log(r)$.

5 Precision and Errors

In the theory of quantum computation (as in the real life) operators, quantum states, etc. are defined with

some precision. Thus, we need to define certain metrics on the corresponding spaces. We will find a natural metric (more specifically, a norm) for each class of objects we deal with: pure and mixed states, unitary and arbitrary gates. After proving some basic properties of these norms, we will show, in a very general form, that error accumulation in quantum computation is at most additive (see Theorem 4 below).

5.1 The Natural Distance Between Probabilistic Functions

We need a measure for the accuracy of the function computed. The natural norm to use is the ℓ_1-norm, called the total variation distance (t.v.d.) between probability distributions. We use t.v.d. to define a metric on probabilistic functions.

definition 7 *Let f, g be probabilistic functions. For input i, f_i, g_i are probability distributions. The total variation distance between f_i, g_i is $|f_i - g_i| \stackrel{def}{=} \sum_j |f_{i,j} - g_{i,j}|$ and $\|f - g\| = max_i |f_i - g_i|$.*

5.2 The Trace Metric on Density Matrices

Precision of a vector $|\xi\rangle \in \mathcal{N}$ (where $\mathcal{N}$ is a Hilbert space) is characterized by the natural (Euclidean) norm $\||\xi\rangle\| = \sqrt{\langle\xi|\xi\rangle}$. Since we have passed to density matrices, we need a metric on general quantum states. There are two natural norms on the space of linear operators on $\mathcal{N}$: the usual operator norm,

$$\|A\| = \sup_{|\xi\rangle \neq 0} \frac{\|A|\xi\rangle\|}{\||\xi\rangle\|} = \text{largest eigenvalue of } \sqrt{A^\dagger A} \tag{2}$$

and the dual norm called the *trace norm*,

$$\|A\|_1 = \sup_{B \neq 0} \frac{|\text{Tr} AB|}{\|B\|} = \text{Tr}\sqrt{A^\dagger A} \tag{3}$$

The norms $\|\cdot\|$ and $\|\cdot\|_1$ are well behaved. Specifically, if $A \in L(\mathcal{N})$ and $B \in L(\mathcal{M})$ then

lemma 10

$$\begin{aligned} \|A \otimes B\| &= \|A\| \|B\|, \\ \|A \otimes B\|_1 &= \|A\|_1 \|B\|_1 \\ \|AB\| &\leq \|A\| \|B\| \\ \|AB\|_1, \|BA\|_1 &\leq \|B\| \|A\|_1 \\ |\text{Tr} A| &\leq \|A\|_1 \end{aligned} \tag{4}$$

(Proof is trivial).

There are many good reasons to use the trace norm as the norm on density matrices (though the operator norm will be very useful in proofs.) First, two pure

states $|\xi\rangle, |\eta\rangle$ which are close in the Euclidian norm are close also in the trace norm:

$$\left\| |\xi\rangle\langle\xi| - |\eta\rangle\langle\eta| \right\|_1 = 2\sqrt{1 - |\langle\xi|\eta\rangle|^2} \leq 2 \left\| |\xi\rangle - |\eta\rangle \right\|$$

The important feature of the trace metric is that it captures the *measurable* distance between different density matrices. It turns out that the trace distance between two density matrices equals the following quantity. For each observable O, a density matrix ρ induces a probability distribution, p_ρ^O, over $i's$. The trace distance between two density matrices is the maximal t.v.d between the two probability distributions, taken over all possible observables.

lemma 11 $\|\rho_1 - \rho_2\|_1 = max_O \left\{ |p_{\rho_1}^O - p_{\rho_2}^O| \right\}$.

Proof: Let $\mathcal{N} = \bigoplus_j S_j$, where the subspaces S_j are mutually orthogonal. Let P_j be the orthogonal projection onto S_j. Then, for any pair of mixed states ρ_1 and ρ_2, $\sum_j \left| \text{Tr}(P_j \rho_1) - \text{Tr}(P_j \rho_2) \right| \leq \|\rho_1 - \rho_2\|_1$. To see this, present the left hand side of this inequality as $\text{Tr}((\rho_1 - \rho_2)B)$, where $B = \sum_j \pm P_j$. It is obvious that $\|B\| = 1$. Then use lemma 10. To see that the trace distance can be achieved by some measurement, let O project on the eigenvectors of $\rho_1 - \rho_2$. ∎

5.3 The Diamond Metric on Quantum Gates

The natural norm on the space of superoperators is

$$\|T\|_1 = \sup_{X \neq 0} \frac{\|TX\|_1}{\|X\|_1}$$

Unfortunately, this norm is not stable with respect to tensoring with the identity. Counterexample: T: $|i\rangle\langle j| \mapsto |j\rangle\langle i|$ $(i, j = 0, 1)$. It is clear that $\|T\|_1 \leq 1$. However $\|T \otimes I_B\|_1 \geq 2$. (Apply the superoperator $T \otimes I_B$ to the operator $X = \sum_{i,j} |i, i\rangle\langle j, j|$). For this reason, we have to define another norm on superoperators

definition 8 *Let T : $L(\mathcal{N}) \rightarrow L(\mathcal{M})$ and $A, B \in L(\mathcal{N}, \mathcal{M} \otimes \mathcal{F})$, where $\mathcal{F}$ is an arbitrary Hilbert space of dimensionality $\geq (\dim \mathcal{N})(\dim \mathcal{M})$.*

$$\|T\|_\diamond = \inf\left\{ \|A\| \|B\| : \text{Tr}_{\mathcal{F}}(A \cdot B^\dagger) = T \right\}$$

This definition seems very complicated. However it is worthwhile using this norm because it satisfies very nice properties, and provides powerful tools for proofs regarding quantum errors. Here are some properties which are satisfied by the diamond norm. The first property is that the diamond norm is the stabilized version of the "naive" norm $\|\cdot\|_1$. The proof of this is complicated and non-trivial. It implies also that $\|\cdot\|_\diamond$ is a norm.

28

lemma 12

1. $\|T\|_\diamond = \|T \otimes I_\mathcal{G}\|_1 \geq \|T\|_1, \ where, \dim\mathcal{G} \geq \dim\mathcal{N}.$

2. $\|T\rho\|_\diamond \leq \|T\|_\diamond \|\rho\|_1.$

3. $\|TR\|_\diamond \leq \|T\|_\diamond \|R\|_\diamond.$

4. $\|T \otimes R\|_\diamond = \|T\|_\diamond \|R\|_\diamond.$

5. The norm of any physically allowed superoperator T is equal to 1.

6. If $\|V\| \leq 1$ and $\|W\| \leq 1$ then $\|V \cdot V^\dagger - W \cdot W^\dagger\|_\diamond \leq 2\|V - W\|.$

Proof of 12.1: It is easy to see that $\|T \otimes I_\mathcal{G}\|_1 \leq \|T \otimes I_\mathcal{G}\|_\diamond \leq \|T\|_\diamond$. The inequality $\|T\|_\diamond \leq \|T \otimes I_\mathcal{G}\|_1$ is not so obvious. W.l.o.g. $\|T\|_\diamond = 1$. We are to prove that $|T \otimes I_\mathcal{G}\|_1 \geq 1$.

We will use the following notation. $D(\mathcal{K})$ denotes the set of density matrices on $\mathcal{K}$, whereas $H(\mathcal{F})$ is the set of Hermitian operators. We can impose the restriction $\|A\| = \|B\| \leq 2$ without changing the infimum in the definition 8. Due to compactness, the infimum is achieved at some A and B. W.l.o.g. $\|A\| = \|B\| = 1$. The quantity $\|A\| \|B\|$ is minimal with respect to infinitesimal variations of the scalar product $\delta\langle\cdot|\cdot\rangle = \langle\cdot|Z|\cdot\rangle$ on the space $\mathcal{F}$. (Here Z is a infinitely small Hermitian operator on $\mathcal{F}$). When computing the variations $\delta\|A\|$ and $\delta\|B\|$, we can restrict A and B to the subspaces $\mathcal{K} = \mathrm{Ker}(A^\dagger A - 1_\mathcal{N})$ and $\mathcal{L} = \mathrm{Ker}(B^\dagger B - 1_\mathcal{N})$. Clearly,

$$\delta\|A\| = \max_{|\xi\rangle\in\mathcal{K}, \, \||\xi\rangle\|=1} \langle\xi|A^\dagger(1_\mathcal{M} \otimes Z)A|\xi\rangle$$

$$= \max_{X\in E}\mathrm{Tr}(XZ)$$

$$\delta\|B\| = \max_{|\eta\rangle\in\mathcal{L}, \, \||\xi\rangle\|=1} -\langle\eta|B^\dagger(1_\mathcal{M} \otimes Z)B|\eta\rangle$$

$$= \max_{Y\in F} -\mathrm{Tr}(YZ)$$

where

$$E = \left\{\mathrm{Tr}_\mathcal{M}(A\rho A^\dagger) : \rho \in D(\mathcal{K})\right\}$$

$$F = \left\{\mathrm{Tr}_\mathcal{M}(B\gamma B^\dagger) : \gamma \in D(\mathcal{L})\right\}$$

Thus, for any $Z \in H(\mathcal{F})$

$$\delta\left(\|A\|\|B\|\right) = \max_{X\in E, \, Y\in F}(\mathrm{Tr}(XZ) - \mathrm{Tr}(YZ)) \geq 0$$

This means that the sets $E, F \subseteq H(\mathcal{F})$ can not be separated by a hyperplane. As E and F are convex and

compact, $E \cap F \neq \emptyset$. Let $\mathrm{Tr}_\mathcal{M}(A\rho A^\dagger) = \mathrm{Tr}_\mathcal{M}(B\gamma B^\dagger) \in E \cap F$, where $\rho \in D(\mathcal{K})$, $\gamma \in D(\mathcal{L})$. Let us represent ρ and γ in the form $\rho = \mathrm{Tr}_\mathcal{G}\left(|\xi\rangle\langle\xi|\right)$, $\gamma = \mathrm{Tr}_\mathcal{G}\left(|\eta\rangle\langle\eta|\right)$, where $|\xi\rangle, |\eta\rangle \in \mathcal{N} \otimes \mathcal{G}$ are unit vectors. Put $X = |\xi\rangle\langle\eta|$. Then $\|(T \otimes I_\mathcal{G})X\|_1 = \|X\|_1 = 1$

Proof of 12.2, 12.3: follow from the relation to the norm $\|\cdot\|_1$ and the definition of the latter.

Proof of 12.4: To prove first direction, $\|T \otimes R\|_\diamond \leq \|T\|_\diamond \|R\|_\diamond$ follows from the definition 8, whereas the inverse inequality follows from 1.

Proof of 12.5: W. l. o. g. $\|T\|_\diamond = \|T\|_1$ (since we can tensor T with the identity). Let $T = \mathrm{Tr}_\mathcal{F}(V \cdot V^\dagger) : L(\mathcal{N}) \to L(\mathcal{M})$. Let us define the dual superoperator $R : L(\mathcal{M}) \to L(\mathcal{N})$ with the property: $\mathrm{Tr}(Y(TX)) = \mathrm{Tr}((RY)X)$ for every $X \in L(\mathcal{N})$ and $Y \in L(\mathcal{M})$. It is obvious that $RY = V^\dagger(Y \otimes I_\mathcal{F})V$ and

$$\|T\|_1 = \sup_{Y\neq 0} \frac{\|RY\|}{\|Y\|}$$

As $\|V\| \leq 1$, the inequality $\|T\|_1 \leq 1$ follows immediately. To prove the inverse inequality, take the identity operator for Y.

Proof of 12.6: To prove this we need lemma 13 from the next section. (For completeness this property appears here). In the definitions of the lemma put $T_1 = V \cdot I$, $T_1' = W \cdot I$, $T_2 = I \cdot V^\dagger$, $T_2' = I \cdot W^\dagger$. ∎

The distance between unitary superoperators $V \cdot V^\dagger, W \cdot W^\dagger$, can be calculated explicitly, and has a geometrical interpretation. Denote by d the distance between 0 and the polygon (in the complex plane) whose vertices are the eigenvalues of $VW^\dagger$. Then

$$\|V \cdot V^\dagger - W \cdot W^\dagger\|_\diamond =$$

$$\max_{\rho\in D(\mathcal{N})} \left\|V\rho V^\dagger - W\rho W^\dagger\right\|_1 = 2\sqrt{1 - d^2}.$$

(The proof is left to the reader).

5.4 Bounding the Overall Error

By definition, the error of a quantum gate is measured by the $\diamond$-norm. The accumulation of errors is bounded by the following lemma:

lemma 13 *Let T_1, T_2 and T_1', T_2' be superoperators with norm ≤ 1, such that $\|T_j' - T_j\|_\diamond \leq \epsilon_j$ $(j = 1, 2)$. Then $\|T_2'T_1' - T_2T_1\|_\diamond \leq \epsilon_1 + \epsilon_2$.*

Proof: Write $T_2'T_1' - T_2 T_1 = T_2'(T_1'-T_1)+(T_2'-T_2)T_1$, and use lemma 12.5 ∎

For subroutines, the natural error measure is different. Fortunately, there is a linear upper bound for the $\diamond$-norm error of a subroutine:

lemma 14 *Let f and f' be two probabilistic subroutines, such that $\|f - f'\| \le \epsilon$. Then $\|g_{f'} - g_f\|_\diamond \le 5\epsilon$. (The superoperator g_f is described in the lemma 5).*

Proof: Let $\mathcal{N}$ be the space of the inputs $|i\rangle$, $\mathcal{M}$ the space of the outputs $|i,j\rangle$. Define the following objects (and their primed versions)

$$A \; : \; \mathcal{N} \to \mathcal{M} \qquad : \; |i\rangle \mapsto \sum_j f_{ij}|i,j\rangle$$

$$B \; : \; \mathcal{N} \to \mathcal{M} \otimes \mathcal{N} \quad : \; |i\rangle \mapsto \sum_j f_{ij}|i,j,i\rangle$$

$$\rho_i = \sum_j f_{ij}|i,j\rangle\langle i,j|$$

$$P_i \; : \; \mathrm{L}(\mathcal{N}) \to \mathcal{C} \; : \; |i_1\rangle\langle i_2| \mapsto \delta_{i_1 i_2}$$

Then $g_f = A \cdot A^\dagger - \mathrm{Tr}_\mathcal{N}(B \cdot B^\dagger) + \sum_i \rho_i P_i$ (the same for $g_{f'}$). Clearly, $\|A'-A\| \le \epsilon$, $\|B'-B\| \le \epsilon$, and the norm of each operator A, B, A', B' does not exceed 1. It remains to show that $\|T\|_\diamond \le \epsilon$, where $T = \sum_i (\rho_i' - \rho_i)P_i$.

Note that $\|\rho_i' - \rho_i\|_1 \le \epsilon$ for each i. Hence $\|(T \otimes I_\mathcal{G})X\|_1 \le \epsilon \sum_i \|Y_i\|_1$, where $\mathcal{G}$ is an arbitrary Hilbert space, $X \in \mathrm{L}(\mathcal{N} \otimes \mathcal{G})$, and $Y_i = (P_i \otimes I_\mathcal{G})X$. On the other hand,

$$\sum_i \|Y_i\|_1 = \left\| \sum_i |i\rangle\langle i| \otimes Y_i \right\|_1 = \|(P \otimes I_\mathcal{G})X\|_1$$

$$\le \|P\|_\diamond \|X\|_1 = \|X\|_1$$

where $P : |i_1\rangle\langle i_2| \mapsto \delta_{i_1 i_2}|i_1\rangle\langle i_2|$ is a physically realizable superoperator. ∎

Due to lemmas 13 and 11, an ϵ error generated somewhere in the circuit can not contribute more than ϵ error to the computed function. This proves the following theorem:

Theorem 4 *Let Q be a quantum circuit which uses L probabilistic subroutines and gates, each with at most ϵ error. The function that Q computes has at most $O(L\epsilon)$ error.*
